Malaria

A B S T R A C T
Malaria has occurred in the Cabo Verde archipelago with epidemic characteristics since its colonization. Nowadays, it occurs in Santiago Island alone and though prophylaxis is not recommended by the World Health Organization, studies have highlight the prospect of malaria becoming a serious public health problem as a result of the presence of antimalarial drug resistance associated with mutations in the parasite populations and underscore the need for tighter surveillance. Despite the presumptive weak immune status of the population, severe symptoms of malaria are not observed and many people present a subclinical course of the disease. No data on the prevalence of sickle-cell trait and red cell glucose-6-phosphate dehydrogenase deficiency are available for the Cabo Verde archipelago and, therefore, we studied allelic frequencies of the polymorphisms examined are closer to European than to African populations and no malaria selection signatures were found. No association was found between the analyzed human factors and infection but one result is of high interest: a linkage disequilibrium test revealed an association of distant loci in the PKLR gene and adjacent regions, only in non-infected individuals. This could mean a more conserved gene region selected in association to protection against the infection and/or the disease.

Introduction

According to de Meira et al. [1] epidemic malaria is known to have occurred in the Cabo Verde archipelago since the remote past. Malaria should have been introduced in the archipelago during its colonization in the XV century. Records from 1507 report that the old Portuguese sailing ships (caravelas) from the spice route were not allowed in Cabo Verde ports because of the fear of getting malaria [2]. In 1952, da Costa Monteiro [3] reported malaria as the most serious public health problem in the archipelago, Santiago being the most affected island.

Cabo Verde is comprised of 10 islands in the Atlantic Ocean, 500 km west of Senegal. Santiago is the largest island, where approximately half of the population resides (capital: Praia). Malaria was almost eradicated between 1954 and 1970 and since 1973 autochthonous cases are only observed in this island [4]. The World Health Organization (WHO) [5] considers there to be a limited risk of malaria between September and November. There is no recommendation for prophylaxis but recent studies highlight the prospect of malaria recurring as a serious public health problem in Cabo Verde and underscores the need for a closer and continuous surveillance. The population is considered to be non-immune or semi-immune and irregular outbreaks occur. An outbreak in 1995–1996 in the St. Catarina district was followed by parasitological and molecular analysis during 1 year [6]. Studies indicated that malaria is maintained as asymptomatic and sub-patent infections and that the majority of the circulating parasite populations harbor chloroquine-resistant mutations [7].

In the previous two studies, no complicated malaria cases were found in spite of high parasitaemias. Most of patent parasitaemias
were above the range of 1000–10,000 parasites/μl, usually considered a cut-off level for malaria attacks [8]. However, individuals of all ages presented no more than mild symptoms such as fever, headache, nausea and general malaise. This population seemed not to develop severe symptoms of malaria despite its presumptive weak immune status and many persons exhibit a subclinical course. The low morbidity associated with malaria infections in this island may be related to factors of both parasites and host, which may control the severity of the malaria infection.

In the localized outbreak in St. Catarina district [6], we suggest that the genetically homogeneous circulating parasite population could have been a weakly virulent parasite. However, when different localities were studied [7] and *Plasmodium falciparum* heterogeneity was observed this hypothesis proved untenable. Therefore, no evidence is available regarding the contribution of parasite factors to the low morbidity observed in the island.

The establishment of clinical symptoms could be attenuated due to premunition, already described for other areas of unstable and low-level transmission of malaria [9,10,11]. Also, differences in clinical consequences of infection with *P. falciparum* as consequence of host factors have already been demonstrated [12,13] and the most common and best characterized protective polymorphisms are those involving the erythrocyte-specific proteins and enzymes, such as hemoglobin (Hb) and glucose-6-phosphate dehydrogenase (G6PD) variants.

Questioning if the observed low morbidity in Santiago Island could be a consequence of particular characteristics of the host population and since no data on the frequency of these human genetic polymorphisms are available for the Cabo Verde archipelago we studied the prevalence of HbS allele responsible for the sickle-cell trait (heterozygosity for the HbS mutation in β-globin gene, Hb β globin) and the prevalence of G6PD variants, two classical genetic factors strongly associated to resistance against human severe malaria.

Further, both may have a crucial importance in the control and management of malaria cases. Malaria can be one of the major causes of hospitalization and death in patients with sickle cell anemia and as a result, antimalarial prophylaxis is included in the standard management of patients with the disease. However, with the spread of chloroquine resistance there is an on-going debate on which drugs should now be used [14]. Concerning G6PD deficiency, the epidemic conditions of *P. falciparum* malaria justify the use of primaquine as a gametocidal drug but this drug presents potentially fatal side effects in G6PD-deficient individuals [15].

In sub-Saharan Africa, X-linked G6PD is essentially a tri-allelic polymorphism: G6PDB, the most common allele associated to normal enzymatic activity; G6PD, which results in approximately 85% of the normal enzymatic activity and the G6PD deficiency allele, which implies only around 12% of normal enzymatic activity with a range of 5–25% in sub-Saharan Africa [16,17]. However, considering the history of Cabo Verde settlement and the reported high European contribution, [18] we also searched for the G6PD Mediterranean (Med) variant, the most common in countries surrounding the Mediterranean Sea [19]. This variant is associated with 3% of normal enzyme activity and usually ranges in frequency from 2% to 20% in Europe [20].

More recently, pyruvate kinase (PK) deficiency was associated with resistance to the disease in rodent models [21] and humans [22,23]. Up to now, elevated frequencies of pyruvate kinase liver and red cells (PKLR)-deficient alleles have not been recorded in areas endemic for malaria, although a systematic analysis has not been done. The information about the frequency of PK deficiency in African populations is clearly limited [24,25]. We, therefore, included its analysis in this study. The PKLR gene (1q21) encodes for either PK-L (in liver) or PK-R (in red cells), according to the use of tissue-specific promoters (leading to structural differences in the protein N-terminal region). The coding region is split into 12 exons, 10 of which are shared by the 2 isoforms, while exons 1 and 2 are specific for the erythrocyte and hepatic isozyme, respectively. About 180 mutations associated with PK-deficiency and 8 polymorphic sites have been reported in the PKLR gene [26].

### Materials and methods

**Study area and Isolates**

Biological material–DNA samples obtained from blood–was already available for this analysis. Samples were collected in localities from different Districts of Santiago Island (Praia–south, St Catarina–west, St Cruz–east and Tarrafal–north) in 1995–1996 [6], 1998–2000 and 2003 [7]. From a total of 1056 available samples, a sub-sample of 257 unrelated individuals was used for the present study (99 individuals from Praia, 23 from St Cruz, 119 from St Catarina and 16 from Tarrafal).

Individual data such as gender, age, and malaria history were available. Further, given that each individual was well characterized for *Plasmodium*-infection (species and genotype) and clinical status (most of them asymptomatic and a few with mild symptoms), two groups were defined: 64 infected (1—presence of infection at least once during the collections period) and 188 non-infected (NI—absence of infection throughout the collection period); infection status was uncertain in 5 individuals.

For the analysis of PK polymorphisms, two additional groups were also analyzed—80 adult healthy Portuguese individuals—PT-C (DNA prepared from finger-prick blood samples collected in 2006 at Health Centre of Coruche, Portugal as described in [27]) and 21 Portuguese individuals with hereditary nonspherocytic hemolytic anemia (HNSHA) caused by PK-deficiency—PT-PKD (DNA prepared from venous blood samples). These PK-deficient individuals were previously diagnosed by PK enzyme assay and molecular genetic analysis [28,29].

The investigation was approved by the Ministry of Health of Cabo Verde and by the Ethical Committee at institutions involved in the study. Each person (or parent) was informed of the nature and aims of the study and told that participation was voluntary.

**Detection of hemoglobin S allele (HbS)**

The mutation at c.6 of the β globin gene was detected using an adaptation of the technique described by Waterfall and Cobb [30] and the homozygous HbSS status was confirmed by a PCR-RFLP technique (details as Supplementary Material).

**Detection of glucose-6-phosphate dehydrogenase polymorphisms**

Mutations in the G6PD gene were detected by a PCR-RFLP method as described in Tishkoff et al. [20] (details as Supplementary Material). The possible nine genotypes were grouped as follows: hemizygous males G6PDDB and G6PDFA, homozygous females G6PDDBB and G6PDAA and heterozygous females G6PDDBA (variants with a putative normal enzyme activity) as g6pd+, hemizygous males G6PDAA and homozygous females G6PDPA A (putative deficient variants) as g6pd− and heterozygous females G6PDPA A and G6PDAA (variants with a putative intermediate enzyme activity) as g6pdL [31].

**Detection of pyruvate kinase polymorphisms**

Analysis of PKLR gene was done by two approaches: (1) typing of polymorphic loci and searching for relevant mutations associated to PK-deficiency previously described and (2) search for new microsatellite regions—short tandem repeats (STRs) in the gene and adjacent regions. In total, a PKLR gene spanning region of 95 kb was analyzed.
Analysis of binary polymorphisms

Two mutations were investigated: 269T–A (90Ile–Asn) at exon 3, the mutation identified in mice as associated to malaria protection [21], and already described in PK-deficient individuals [32] (technical details as Supplementary Material) and 1456C–T (846Arg–Trp) at exon 11, the most common mutation responsible for PK deficiency in humans from Portugal and some Sub-Saharan regions [33,34,35]. Also, two polymorphisms were analyzed: the single nucleotide polymorphism (SNP) 1705A/C at exon 12 [35,36], and the T10/19 repeat at intron 10 [37], common polymorphic sites in São Tomé e Príncipe [24].

Analysis of STRs

After searching for STRs in the PKLR gene (accession nr AY316591) and downstream/upstream adjacent regions (accession nr AL713999), 4 loci were chosen for analysis: 2 inside (intron 3–IVS3 and intron 11–IVS11) and 2 downstream the gene (25 kb–locus PKA and 65 kb–PKV). IVS11 was the only one already described as polymorphic [38] (see Supplementary Material for amplification conditions and analysis of PCR products).

Statistical analysis

Pearson χ² test was used for comparison of populations from different districts and malaria I and NI groups. Additionally, PK polymorphisms were also compared with the two Portuguese groups, PT-C and PT-PKD. Allelic frequencies and selection signatures were investigated (genetic diversity, Hardy–Weinberg equilibrium deviation and linkage disequilibrium) with Arlequin 3.11. for Windows [39]. For all tests, a significance level of 0.05 was considered.

Results

Hemoglobin polymorphisms

The β globin genotype was successfully defined for a total of 217 individuals (84%). From these, 92% were HbAA, 7% HbAS and 1% HbSS. HbS allele was only found in Praia (11% of HbAS) and St Catarina (4% of HbAS and 3% of HbSS) districts with a very low frequency (0.05). I and NI individuals distributed similarly among HbAA and HbAS genotypes [21% I and 79% NI in the HbAA group (unknown infection status of 3 individuals) and 23% I and 77% NI in the HbAS group (unknown infection status of 1 individual)]. All 3 HbSS individuals were I.

Glucose-6-phosphate dehydrogenase polymorphisms

G6PD genotype was measured in a total of 176 (68%) individuals, 77 males and 99 females. Seventy-four percent of males presented G6PDAB genotype, 25% G6PDAA and 1% G6PD−; 61% of females presented G6PDBB genotype, 29% G6PDAB, 6% G6PDAA and 4% G6PD− (no genotypes G6PDBA and G6PD− A were found).

In the total population, allelic frequencies were f(B) = 0.95, f (A) = 0.04 and f(A−) = 0.008, respectively but A− allele was only found in Praia and Tarrafal districts, being much more frequent in the latter—0.019 and 0.115, respectively (P = 0.007), which reflected the presence of 3 G6PDAA− genotypes. G6PDMed variant was not found.

Ninety-seven percent of individuals were G6PD+, 2% were G6PD− and 1% were G6PD−. Normal condition seems to be equally prevalent in both genders (99% G6PD+ in males and 96% in females); 1% and 0% of G6PD− in males and females, respectively and 4% of G6PD− in females.

Among A− carriers, all except one G6PDAA− female were NI. I and NI individuals distributed similarly among G6PD+ and G6PD− groups [33% I and 64% NI in the G6PD+ group (unknown infection status of 5 individuals) and 25% I and 75% NI in the G6PD− group]. The only G6PD− individual was NI.

Pyruvate kinase polymorphisms

Binary polymorphisms

The 269T–A (exon 3) and 1456C–T (exon 11) mutations were screened in subjects with the greatest diversity indices with the larger allele number and expected frequencies. G6PD genotype was measured in a total of 176 individuals (68%), and already described in PK-deficient individuals for Portugal and some Sub-Saharan regions (33,34,35). Also, two polymorphisms were analyzed: the single nucleotide polymorphism (SNP) 1705A/C at exon 12, common polymorphic sites in São Tomé e Príncipe [24].

Analysis of binary polymorphisms

Two mutations were investigated: 269T–A (90Ile–Asn) at exon 3, the mutation identified in mice as associated to malaria protection [21], and already described in PK-deficient individuals [32]; technical details as Supplementary Material) and 1456C–T (846Arg–Trp) at exon 11, the most common mutation responsible for PK deficiency in Portugal and some Sub-Saharan regions [33,34,35]. Also, two polymorphisms were analyzed: the single nucleotide polymorphism (SNP) 1705A/C at exon 12, common polymorphic sites in São Tomé e Príncipe [24].

Statistical analysis

Pearson χ² test was used for comparison of populations from different districts and malaria I and NI groups. Additionally, PK polymorphisms were also compared with the two Portuguese groups, PT-C and PT-PKD. Allelic frequencies and selection signatures were investigated (genetic diversity, Hardy–Weinberg equilibrium deviation and linkage disequilibrium) with Arlequin 3.11. for Windows [39]. For all tests, a significance level of 0.05 was considered.

Results

Hemoglobin polymorphisms

The β globin genotype was successfully defined for a total of 217 individuals (84%). From these, 92% were HbAA, 7% HbAS and 1% HbSS. HbS allele was only found in Praia (11% of HbAS) and St Catarina (4% of HbAS and 3% of HbSS) districts with a very low frequency (0.05). I and NI individuals distributed similarly among HbAA and HbAS genotypes [21% I and 79% NI in the HbAA group (unknown infection status of 3 individuals) and 23% I and 77% NI in the HbAS group (unknown infection status of 1 individual)]. All 3 HbSS individuals were I.

Glucose-6-phosphate dehydrogenase polymorphisms

G6PD genotype was measured in a total of 176 (68%) individuals, 77 males and 99 females. Seventy-four percent of males presented G6PDAB genotype, 25% G6PDAA and 1% G6PD−; 61% of females presented G6PDBB genotype, 29% G6PDAB, 6% G6PDAA and 4% G6PD− (no genotypes G6PDBA and G6PD− A were found).

In the total population, allelic frequencies were f(B) = 0.95, f (A) = 0.04 and f(A−) = 0.008, respectively but A− allele was only found in Praia and Tarrafal districts, being much more frequent in the latter—0.019 and 0.115, respectively (P = 0.007), which reflected the presence of 3 G6PDAA− genotypes. G6PDMed variant was not found.

Ninety-seven percent of individuals were G6PD+, 2% were G6PD− and 1% were G6PD−. Normal condition seems to be equally prevalent in both genders (99% G6PD+ in males and 96% in females); 1% and 0% of G6PD− in males and females, respectively and 4% of G6PD− in females.

Among A− carriers, all except one G6PDAA− female were NI. I and NI individuals distributed similarly among G6PD+ and G6PD− groups [33% I and 64% NI in the G6PD+ group (unknown infection status of 5 individuals) and 25% I and 75% NI in the G6PD− group]. The only G6PD− individual was NI.
other. No conspicuous differences seemed to exist regarding allelic frequencies or inferred haplotypes except that it is the only district when IVS3 observed heterozygosity was according to Hardy–Weinberg expected frequencies.

Regarding the studied Portuguese groups—PT-C and PT-PKD, IVS3 locus also presented the greatest diversity indices with the larger allele number and expected heterozygosity (Table 2). Observed heterozygosity was according to Hardy–Weinberg expected frequencies for all loci in the PT-C but not in PT-PKD. In this one, both IVS3 and IVS11 were significantly below the expected (P = 0.000 and P = 0.002, respectively). Again excluding IVS3 from the analysis, PT-C only showed LD for the closer loci (PKV/PKA and PKA/IVS11), while PT-PKD just had LD for PKV/IVS11 but since this latter, as IVS3, was not in Hardy–Weinberg equilibrium, we may say that no LD was observed between loci in this group.

When FST values were calculated for the two Portuguese groups, a significant value was obtained (0.025, P = 0.009). When those were calculated for all the studied populations pairs, significant values (P = 0.000) were obtained for all: CV-Total vs. PT-C—0.068 and vs. PT-PKD—0.111; CV-St Cruz vs. PT-C—0.111 and vs. PT-PKD—0.170; CV-I. St Catarina vs. PT-C—0.076 and vs. PT-PKD—0.122; CV-NI-St Catarina vs. PT-C—0.076 and vs. PT-PKD—0.124.

When groups of I and NI from St Catarina, which have similar sample sizes (I—112 alleles and NI—118), were compared, the same was observed—a marked LD between all pair of loci in the overall population and NI alone and no linkage between IVS11 and PKV in the I. Besides, I and NI from St Catarina revealed no significant differences between them but IVS3 observed heterozygosity was according to Hardy–Weinberg expected frequencies in the I group.

Discussion

The study of malaria epidemiology is crucial for control, especially in countries like Cabo Verde where mosquito vectors are in close proximity to susceptible host populations and tourists. In Cabo Verde, we are addressing the three biological entities involved in the complex malaria life-cycle doing both parasitological [6,7] and entomological studies (on-going). The present study addresses some human host genetic polymorphisms in association to malaria.

Sickle cell disease affects millions of people worldwide and it is most common among people whose ancestors come from sub-Saharan Africa, India, Saudi Arabia and Mediterranean countries. Frequencies of the heterozygous state for the sickle cell gene (HbAS) range from 2% to 38% in sub-Saharan Africa where HbS allele frequencies frequently exceed 25% [14,16,40]. Sickle-cell trait is the best described host-specific factor shown to confer strong protection against P. falciparum in numerous studies over the course of the last 50 years [41,42,43,44].

Deficient G6PD alleles are distributed worldwide with a global prevalence of deficiency of 4.9% and an estimate of nearly 330 million people carrying a deficiency-associated mutation in the G6PD gene when were analyzed separately (St Cruz—46 alleles and Tarrafal—32 alleles). However, when I and NI from St Catarina, which have similar sample sizes (I—112 alleles and NI—118), were compared, the same was observed—a marked LD between all pair of loci in the overall population and NI alone and no linkage between IVS11 and PKV in the I group. Besides, I and NI from St Catarina revealed no significant differences between them but IVS3 observed heterozygosity was according to Hardy–Weinberg expected frequencies in the I group.

PT-C: Portuguese healthy individuals; PT-PKD: Portuguese individuals with hereditary nonspherocytic hemolytic anemia (HNSHA) caused by PK-deficiency; Obs: Observed Heterozygosity; Exp: Expected Heterozygosity; P: P-value.
The highest prevalence is reported in Africa, southern Europe, the Middle East, Southeast Asia, and the central and southern Pacific islands; however, because of fairly recent migration, deficient alleles are nowadays quite prevalent in North and South America and in parts of northern Europe [19]. In most areas of high prevalence of G6PD deficiency, several polymorphic alleles are found but tropical regions of Africa are one exception, where the variant G6PD A* accounts for about 90% of G6PD deficiency with frequencies of 5–25% [16,17]. The coincident worldwide distribution of malaria and mutated G6PD alleles made “The malaria/G6PD hypothesis” generally accepted [46]. Further evidence of protection against severe P falciparum malaria comes from both epidemiological studies [47] as well as from in vitro work [48,49].

PK deficiency along with G6PD deficiency, are the two most frequent enzyme disorders causing chronic hemolytic anemia worldwide. In families with no consanguinity, PK-deficient individuals are usually compound heterozygotes and prevalence of heterozygous individuals is estimated to be 1–2% in most studies [50]. The highest frequencies of the PK deficiency associated alleles are found in Europe and Asia with a prevalence ranging from 1% to 3.6% [26,33]. As these regions were historically endemic for malaria, it could have been responsible for maintaining this frequency or the 180 mutations resulting in PK-deficiency are simply the product of random variation or other population genetic phenomena. However, in Africa, although the prevalence of PK deficiency is not known, the perception exists that it is rare, which may reflect a lack of testing [23]. If the marked in vitro protective effect of homozygosity for PK deficiency against malaria translates into the field (further supported by the murine model data), the argument that malaria has maintained the polymorphic frequency of the abnormal alleles may be plausible. In addition, the large number of PKLR mutations per se also suggests that these have been maintained by a selective force [23].

In the present study of the β globin chain of Hb, 6% of HBs individuals and a frequency 0.05 of HBS allele are low values for a sub-Saharan region. Also G6PD deficiency associated mutations occurs in a very low frequency in this population (0.6%). Concerning PKLR polymorphisms, frequencies of alleles or haplotypes also differ from those described for African populations. Allelic frequencies of polymorphism 1705A/C (f(A) = 43%, f(C) = 57%) are closer to the European populations (f(A) = 29%, f(C) = 71%) than to Saharawi population from North Africa (f(A) = 62%, f(C) = 38%) or sub-Saharan populations (f(A) = 67%, f(C) = 33%) [25]. Allelic frequencies of the repeat (T10/19) [f(T10) = 53%, f(T19) = 47%] are closer to the Portuguese population [f(T10) = 78%, f(T19) = 22%] than to São Tomé e Príncipe (Gulf of Guinea, West Africa) [f(T10) = 36%, f(T19) = 64%] [24]. Allelic frequencies of all these polymorphisms seem always closer to the European, particularly to the Portuguese populations. The most frequent haplotypes 1705C/T10 and 1705A/T19, were the only two observed in Portugal and Central Europe [37]. However, the other two, 1705A/T10 and 1705C/T19 also occurred in low frequencies. As in São Tomé e Príncipe [24], there is a strong but not total association for combinations among these two biallelic systems.

Such low frequencies of traits Hbs and G6PDMD are somehow unexpected. It could be due to the already well known importance of Caucasian admixture in the population of Cabo Verde [18] but these traits are quite prevalent in the Mediterranean region, an endemic region for malaria in the past. Further, Santiago Island should have had less contribution from Caucasians as demonstrated before in previous studies with mtDNA [51], Y-chromosome lineages [52] and autosomal STR [53]. Nevertheless, particular settlements with a strong African contribution to the genetic composition of the population seemed to persist as it may be the case of St Cruz. This district located in the east coast of the island showed FST values significantly different with all other studied populations both considering loci 1705A/C and (T10/19 or STRs analysis. Moreover, allelic frequencies of the first two loci (f(A) = 57%, f(C) = 43%; f(T10) = 39%, f(T19) = 61%) were closer to the Saharawi population from North Africa and São Tomé e Príncipe (see above). Although we do not have historical reports about St Cruz or its capital Pedra Badejo (former Port of São Tiago), it is commonly said that the escaping slaves (Cabo Verde became an important provisioning station for slaves headed for the Americas) used to hide in this area, from where they could escape to the Island of Maio. This could justify such a stronger African contribution for the genetic background of this population but this should be further analyzed with more balanced sample sizes.

In the present study, no malaria related clinical data were available but regarding the infection status no association seems to occur with either the Hb β globin or the G6PD genotype. Also no haplotype or polymorphism of PKLR gene was associated to infected or non-infected individuals. Nevertheless some striking results related with PKLR analysis deserve a special remark. A linkage disequilibrium test revealed an association of distant loci only in non-infected individuals. This could mean a more conserved gene region in these individuals, which could happen if it would confer any protection against the infection and/or disease. Further, other peculiarities were found in the two groups. Infected individuals from St Catarina showed a significantly higher heterozygosity than expected in the locus T10/19 and on the opposite, it was the only group where IVS3 observed heterozygosity was within Hardy–Weinberg expected frequencies. Non-infected individuals from this district showed inverted allelic frequencies of the locus T10/19 comparing to the general trend and haplotypes 1705C/T10 and 1705A/T19 presented similar frequencies and 1705C/T19 showed higher frequency than in other studied groups. Further studies are needed to assess if these findings have a real biological meaning or are simply sampling artifacts.

Concluding remarks

This was the first study where data on sickle cell trait and G6PD deficiency frequencies were obtained for Cabo Verde human populations.

In this study no association was found between the analyzed human genetic factors and infection status of individuals. Three main reasons may have contributed for this: (1) the role of erythrocyte polymorphisms are usually associated and much easier demonstrated in severe than in mild or asymptomatic cases [54], (2) the cross-sectional sampling makes the infected/non-infected classification a faint case definition for an association study and 3) selective pressure of malaria, even if it had occurred, could never had a strong effect in this area due to its epidemic character.

Nevertheless, the finding of a very low frequency of G6PD deficiency associated alleles (A− and MED) have important implications for the malaria control strategies defined by the National Program to Fight against Malaria (Programa Nacional de Luta contra o Paludismo, PNLP) viewing that it is recommended by WHO [55] that primaquine (potentially lethal in G6PD-deficient individuals) should be added to the drug regimen to block transmission in epidemic conditions such as Cabo Verde.

Regarding the PKLR gene, responsible for PK deficiency, recently reported as conferring protection against malaria in rodent and in vitro models, this study has not shown any clear association with malaria infection. Selective advantage afforded individuals protection from severe life-threatening complications of malaria and did not necessarily decrease their susceptibility to infection. Further, pyruvate kinase deficiency is a heterogeneous condition and most of the clinical phenotypes are mild or moderate in severity [26]. This suggests that the reproductive cost of PK deficiency was not limiting and mutations/polymorphisms would be spread in apparently healthy individuals.

Nevertheless, this is, to our knowledge, the first genetic population study about this putative association and results such as the region in linkage identified in the non-infected group deserve further investigation. Also, to further assess the assumption of a
protective effect of PK deficiency, further studies are being performed in other African populations from malaria highly endemic areas with well-defined malaria clinical cases (different severity level), well-characterized Plasmodium-infection and Hb β-globin and G6PD status (to control for negative epistasis) and immediate enzymatic activity dosage at collection.

Acknowledgments

We are grateful to the population of Santiago Island, Cabo Verde who accepted to collaborate in this study. We thank the Health Delegates and technicians of Health Care Units of St Cruz, Tarrafal, St Catarina (especially Ana Veiga, Aníbal Monteiro, António Monteiro and Edna Semedo) and Praia (especially Ernesto Cabral, Jorge de Pina (National Program against Malaria, Cabo Verde), Encarnação Horta and Marta Remédios (Institute of Hygiene and Tropical Medicine, Portugal) for technical assistance. We are also grateful to Doutor João Pinto for his participation in some sampling periods.

This study was supported by ‘Financiamento Programático do Laboratório Associado CMTDLA/IMHT’, POCTI—Programa Operacional Ciência e Inovação 2010 (IPATIMUP) and POCT/SAU-ESP/S5110/2004 (FCT/MCTES, Portugal). J. Alves and A.P. Ares were funded by FCT/MCTES Portugal (SRFH/BD/153451/2005 and SRHF/BDP/1624/2000 until 2007, respectively).
